Abstract

Neuroimaging biomarkers have potential role in the early diagnosis as well as periodic follow-up of neurodegenerative diseases such as Alzheimer’s disease (AD). Structural imaging biomarkers can be used to predict those who are at risk or in preclinical stages of AD. It could possibly be useful even in predicting the conversion of Mild Cognitive Impairment (MCI) an early stage of AD to AD. In addition there has been a lot of progress in molecular imaging in AD. This article presents a review of recent progress in selected imaging biomarkers for early diagnosis, classification, and progression, of AD. A comprehensive integrative strategy initiated early in the cognitive decline is perhaps the most effective method of controlling progression to Alzheimer’s disease.

INTRODUCTION

Alzheimer’s disease (AD) is the most common cause of dementia among people aged 60 years and older.1 The prevalence of AD ranges from 6.44% in south India2 to 4.86% in Shanghai,3 China to 3.92% in Sri Lanka for populations above 65 years.4 The main clinical feature of AD is increasing memory impairment followed by impairment of other cognitive domains, a characteristic pathological cortical and hippocampal atrophy, histological feature of senile plaques of amyloid deposits and neurofibrillary tangles consisting of intraneuronal tau fibrillary tangles.5

The prevalence of AD is expected to increase dramatically as the population around the globe continues to age. Better understanding of this dementing disease, therefore, is essential, and early diagnosis combined with a comprehensive management strategy initiated early in the course of the cognitive decline will likely be the most effective method of controlling the progression of AD.6-8 Currently one of the major handicaps towards achieving this is the difficulty in early and definitive diagnosis of AD. Over the past decade there has been a tremendous amount of research output in the field of biomarkers of AD. Structural MRI studies and functional studies such as PET and SPECT are being widely researched in the diagnosis of AD.9-11 Structural and functional imaging may be useful for the early diagnosis of AD.12,13 With increasing research in disease modifying therapy in AD and recognition of mild cognitive impairment (MCI) as a very incipient stage of AD, early diagnosis of AD will assist in early initiation of disease modifying therapy. This in turn will aid in improving the quality of life of patients with AD.

Mild cognitive impairment

MCI is a predementia condition that has been shown to have a high likelihood of progression to AD.14,15 It is characterized by impairment in one domain of cognition with relatively preserved other cognitive domains in the presence of unimpaired functional abilities.16,17 MCI can be categorized as amnestic MCI (aMCI) and non-amnestic MCI (naMCI). aMCI refers to patients who are functionally independent but with impairment in the memory domain. Whereas naMCI includes functionally independent patients with impairment in one or more non-memory domains of cognition such as attention, executive functioning, language and visuospatial processing etc. Some studies suggests that patients with the aMCI subtype have a higher risk of progression to AD.18
NEUROIMAGING BIOMARKERS FOR EARLY DETECTION OF ALZHEIMER’S DISEASE

Neuroimaging biomarkers

Biomarkers have diagnostic and prognostic value in the early detection of AD. Research is ongoing in a wide spectrum of biomarkers (Figure 1) associated with AD. Among these, possibly neuroimaging has the potential for predicting the transition from MCI to AD. Several brain-imaging techniques are often used for studying the neuropathological processes and morphological and functional changes occurring in AD. Neuroimaging methods are helpful not only in the early diagnosis but also in differentiating AD from other neurodegenerative diseases. Studies have revealed that imaging techniques can be used for the prediction of conversion of MCI to AD. Neuroimaging techniques can be mainly classified as structural and functional. The main structural imaging techniques are computed tomography (CT) and magnetic resonance imaging (MRI). The CT imaging technique provides high resolution and has the ability to distinguish two structures from each other as separate. However, MRI imaging technique, due to its high spatial resolution can be used to distinguish the difference between two arbitrarily similar but not identical tissues. Other techniques such as positron emission tomography (PET), single photon emission computed tomography (SPECT), and functional MRI (fMRI) are examples of functional neuroimaging techniques. Even though functional imaging technique provides some structural information; their spatial resolution is lower than structural imaging technique.

STRUCTURAL IMAGING TECHNIQUES

Computed tomography (CT)

CT is not used as a standard technique for early diagnosis of AD. CT is mainly used to rule out potentially surgically treatable causes of dementia such as tumors and sub-dural hemorrhage, etc. In AD, the CT scan analysis may reveal diffuse cerebral atrophy with enlargement of the cortical sulci and increased size of ventricles. However, these are late changes in AD. Some studies have suggested that, medial temporal lobe atrophy could predict the earlier detection of AD. The main advantages of this imaging technique is that, it may help in the differential diagnosis of dementia, such as ruling out a paramedian tumor or a normal pressure hydrocephalus. In developing resource constrained nations, it is also less expensive, faster and more widely available than MRI. Other than the afore mentioned, CT does not have any role in the early diagnosis of AD.

Structural magnetic resonance imaging

MRI is one of the non-invasive imaging techniques for the structural analysis of AD brains. Frisoni and colleagues demonstrated convincingly the phenomenon of medial temporal lobe atrophy as an early marker in AD. The decline from normal to MCI and to AD has been investigated mainly using MRI studies. Most of the MRI studies demonstrated that atrophy of the medial temporal lobe structures (hippocampus, and entorhinal cortex) is common in AD. Structural MRI analysis has demonstrated that medial temporal atrophy is associated with increased risk of developing AD and can predict future memory decline in healthy adults. Current
research focuses on some of the volumetric analysis techniques for the early detection of AD.\textsuperscript{33,34} Earliest technique was the visual impression which evolved to manual volumetry and later into automated volumetry. Volumetric analysis of MRI can detect significant changes in the size of brain regions. Regional atrophy measurement during the progress of AD is a potentially promising diagnostics indicator.\textsuperscript{35,36} The various volumetry assessment tools and methods are listed in Table-1.

Volumetric methods are quantitative and have been used to demonstrate significant differences in volumes of specific medial temporal lobe structures, such as the hippocampus and amygdala among cognitive diagnostic groups.\textsuperscript{27,37,38} The manual volumetric technique requires an excellent working knowledge of neuroanatomy as well as good skill in delineating regions of interest (ROI). Manual volumetry is a very time consuming process compared to automated volumetric methods. Voxel based morphometry (VBM) is an automatic volumetric approach, which allows distinguishing between healthy controls and patients (Figure 2) based on the volume of brain and region of interest.\textsuperscript{39-41} IBASPM and MarsBar are the toolboxes of SPM to distinguish an AD group from a normal control group. Free surfer and FMRIB Software Library (FSL) (http://www.fmrib.ox.ac.uk) make available brain region templates for the automated methods that can detect hippocampal atrophy in patients and provide information about the shape, position or volume of brain tissue.\textsuperscript{40}

Recent VBM techniques have demonstrated that in subjects who converted from MCI to clinical AD, atrophy not only involved the MTL but also widespread neocortical regions when compared to the cognitively stable MCI subjects.\textsuperscript{37}

### Diffusion tensor imaging

Diffusion tensor imaging (DTI) is the advanced MR Imaging technique, which uses MRI to measure non-random movement of water molecules. It can thus track the fibers of tracts within the brain. There are reports that DTI can detect early microstructural alterations in AD patients before gross anatomic alterations become

visible, alterations, which are generally not detected by conventional MRI.\textsuperscript{42} In DTI, the main parameters measured are Fractional Anisotropy (FA), apparent diffusion coefficient (ADC) and mean diffusivity (MD). Fiber tract integrity provides a direct assessment of white matter fibers and could be potentially used as a biomarker for AD.\textsuperscript{43} Anisotropy means the movement of water molecules is greater lengthwise along neural tract relative to their movement across tract width. In any disruption in the axon, water molecules moves more randomly through the tissues causes a reduction in anisotropy that characterizes AD. ADC describes the interaction of the diffusing molecules with cellular structures and to detect the overall diffusivity. The characteristic of mean diffusivity is same as that of ADC characteristics. The importance of DTI in neuroimaging is to be able to provide ROI analysis, three dimensional visualization, color mapping, fiber tracking and computerized approach for tensor calculation.\textsuperscript{44,45}

A clinical application of DTI could be to assess the differential diagnosis of dementia (AD and vascular dementia) using the DTI based tensor maps.\textsuperscript{46} Region based DTI analysis results shows that hippocampal microstructural changes could be a better predictor of risk of progression of MCI to AD.\textsuperscript{47} In DTI it is possible to analyze the connectivity and plastic organization of the human brain. Some reports suggest that the main DTI parameters FA and ADC values could be possibly used as AD biomarkers.\textsuperscript{48,49}

### Functional Imaging Techniques

#### Functional MRI (fMRI)

Functional MRI (fMRI) is a noninvasive imaging technique for functional analysis. This neuroimaging technique could be used to monitor AD patient’s treatment.\textsuperscript{50} fMRI is a useful method to characterize the functional abnormalities in dementia subjects. It measures the oxygen concentration of certain specific brain areas corresponding to particular stimuli or cognitive tasks.\textsuperscript{51,52} This technique has high spatial and temporal resolutions. In brief the principle of fMRI consists of acquisition of brain images during a specific brain activity and in a basal state. During analysis, the basal state activity is subtracted from the specific task activity to yield the specific brain areas where blood flow had increased due to the blood oxygen level dependent (BOLD) response\textsuperscript{53} during the performance of the specific task by the brain. Resting and activation state of fMRI studies show that AD patients have lesser-coordinated activity in the hippocampus, inferior parietal lobes and cingulate cortex compared with healthy controls.\textsuperscript{50,54} Recent advances in fMRI have helped to identify the neural substrate for cognitive behavioral functions in early phases of neurodegenerative disorder and correlated them with neuroanatomical network.\textsuperscript{55}

#### Molecular and beta-amyloid imaging

Molecular imaging technique aims to diagnose AD in its earliest stages. This technique determines the disease changes at molecular level in the brain. The results of several clinical trials indicates
that PET imaging of amyloid plaques can identify patients destined to develop AD several years before the development of dementia.\textsuperscript{56,57} Recently, radiotracers for amyloid plaques have shown the presence and extent of plaques in the brain.\textsuperscript{58} This could allow for early detection of AD. Direct imaging of amyloid load in a brain with AD would be useful for the early diagnosis of AD and the development and assessment of new treatment.\textsuperscript{59} Currently used molecular imaging compounds in AD research include the following.\textsuperscript{60}

\textit{Pittsburgh compound B}: Pittsburgh compound B (PIB) was the first radiotracer used by Klunk and colleagues for highlighting deposits of beta amyloid plaques.\textsuperscript{61} It helps to visualize the pathological hallmark of AD in living individuals during a PET scan. PIB is a fluorescent analog of thioflavin T, which can be used in PET scans to image beta amyloid plaques in neuronal tissue. PIB may be used in investigational studies of AD.\textsuperscript{62,63}

\textit{Florbetapir F 18}: Florbetapir F 18 (18F-A V-45) is a novel radiotracer. It is a novel tracer for PET imaging of $\beta$ amyloid plaques in the brain of AD patients.\textsuperscript{64}

\textit{Florbetaben}: Florbetaben (BAY 94-9172) is a radiotracer designed to detect beta amyloid during PET scan.

\textit{18F flutemetamol}: 18F flutemetamol (Flute) is a radiotracer for PET scan that is structurally identical to PIB except for one fluorine atom in place of a carbon atom.

PIB-PET technique is the most extensively and best validated tracer. Negative amyloid scans indicate absence of AD with high accuracy, but healthy elderly controls have positive amyloid scans whose predictive value in isolation is less clear. PIB-PET is a powerful imaging technique, to examine the relationship between clinical symptoms, amyloid deposition and structural and functional brain changes between the controls and AD patients.\textsuperscript{55,66} Accumulation of the $\beta$ amyloid peptide in the brain is a hallmark of AD. Amyloid imaging can identify patients with MCI who have A-beta aggregation in the early stage (Figure 3). Amyloid imaging consists of an injection of a radiolabel led ligand targeting amyloid aggregates and use of PET technology to acquire images of the brain in order to display foci of abnormal amyloid accumulation. This technique will possibly provide an increase in the diagnostic accuracy of AD in the near future. In future, amyloid imaging will possibly be considered as a biomarker for AD and this can be useful for drug development and to clarify their prognostic and diagnostic power in relation to age, risk factors, and AD

\begin{figure}[h]

\includegraphics[width=\textwidth]{figure3.png}
\caption{FDG and PIB PET images for Alzheimer's disease patient and normal controls (Modified from Mistur et al.)}
\end{figure}
There is evidence, however, from the Australian Imaging Biomarkers and Lifestyle (AIBL) study, that the total amyloid burden alone does not alone play a role in hippocampal atrophy and cognitive decline, just as there is evidence that the amyloid burden in the temporal neocortex is related to hippocampal atrophy even in nondemented elderly subjects.

**Positron emission tomography**

Positron emission tomography (PET) is a powerful imaging technique, has been used to investigate functional alterations of the brain both in healthy and ill subjects. PET scanning is a molecular imaging technique that allows physicians to obtain three-dimensional images of what is happening in a patient’s brain at the molecular and cellular level. Studies have suggested that PET is very accurate at diagnosing AD and differentiating it from other dementias. Regional cerebral metabolism studies with PET have used 18F-2fluoro-2-deoxy-D-glucose (FDG) as a metabolic marker in early diagnosis and preclinical detection of dementia. FDG PET measures the glucose metabolism in different regions of the brain. This technique can be used to identify the causes of dementia and to have a differential diagnosis, as well as, predict conversion to AD in patients with MCI. On FDG–PET examinations, severe reductions in the rate of brain glucose consumptions in AD patients as compared to normal elderly have been shown. FDG –PET studies report that AD patients show regional metabolic reductions involving the parietal-temporal and posterior cingulate cortices and the frontal areas in advanced disease. It has been assumed that metabolic change associated with neocortical dysfunctions may be detectable by FDG-PET before atrophy appears. FDG-PET provides closer relation to clinical symptoms, but it is less sensitive in preclinical disease PIB-PET imaging seems more capable to detect early changes in progression of AD than FDG-PET imaging given its correlation with measures of cognitive testing and hippocampal atrophy by MRI. In future a combination of FDG and PIB-PET technique may be more useful in predicting short-term conversion to AD. In AD, FDG-PET imaging techniques often showed the reduced use of glucose in brain areas which are important in memory, learning and problem solving.

**Magnetic resonance spectroscopy (MRS)**

Magnetic resonance spectroscopy (MRS) is a non-invasive imaging technique for assessing metabolic and molecular correlates of dementia. It provides vital biological information at the molecular level. MRS technique can predict future progression to AD in patients with MCI and tracking disease progression. In future H1 MRS has a potential role in early and differential diagnosis of dementia. Proton MRS detect normal metabolic pattern in patients with mild neurological impairment and severe brain abnormalities. However quantitative measurement of regional brain volume can be useful in the diagnosis of dementia. Proton MRS can provide useful information to differentiate between AD and other dementias. Magnetic resonance spectroscopy has proven useful to monitor disease progression in early AD. MRS of the hippocampus and other cortical areas could predict conversion from amnestic mild cognitive impairment to probable AD. Pedro and colleagues suggests that H-MRS of the occipital cortex may be valuable tool in predicting conversion from MCI to probable AD.

**Single photon emission computed tomography (SPECT)**

SPECT is a molecular imaging technique; It uses highly targeted radiotracers to detect cellular or chemical changes linked to specific disease. The technique for evaluation of brain perfusion uses a rotating gamma camera. SPECT imaging aids in the differential diagnosis of patient with dementia. SPECT imaging could serve as a tool to make accurate diagnosis and measure the progression of changes in the brain. Beta amyloid imaging technology can discriminate individuals with AD. The amount of beta amyloid protein detected in the brain reflect the severity of symptoms of memory loss. The combination of SPECT and PET Imaging studies could help to identify and evaluate patients from early to late in the disease. The development of specific imaging agents for direct mapping of A-beta plaques in the living brain is a great challenge. Currently the use of PIB in combination with PET allows the imaging of beta amyloid plaques in the brain that are indicative of AD. 18Fflutemetamol combined with PET imaging can detect probable early stage AD and MCI. Amyloid imaging may help in the early detection of the disease. SPECT is a cheaper method than PET but less specific.

**Magnetic encephalography (MEG)**

Magnetic encephalography (MEG) is a noninvasive neuroimaging technique for measuring the
magnetic field patterns generated by the brain. Hence, it may help to understand the relationship between brain function and cognition. It is possible that future research could reveal that in AD, MEG could serve as a potential biomarker and could be used for the differential diagnosis. Moreover, MEG shows particular promise in predicting the development of MCI from normal cognition. Some studies have reported that individuals with subjective memory complaints showed higher MEG activation than controls. Spontaneous MEG activity shows increased slow rhythms and reduced fast activity in AD patients compared with healthy subjects. Some studies suggest that the presence of low frequency magnetic activity associated with AD pathology. Studies suggested that low frequency in temporoparietal regions plays a key role in the transition of MCI to AD. Studies estimated the MEG oscillations to detect changes in subject with MCI in the earliest preclinical stages of dementia. MEG is capable of detecting alterations in the functional organizations of the central nervous system. MCI subject has showed decreased mean frequency MEG power spectrum as compared to healthy controls and AD patients.

CONCLUSION
The development of neuroimaging technique for AD has the ability to detect clinical or pathological change overtime. Neuroimaging techniques have important role in research and clinical practice. Advances in structural and functional neuroimaging techniques allow detection of AD, years before the symptoms of dementia develop. A recent major advance is the development of amyloid imaging techniques that allows in vivo identification of amyloid deposition in the brain. Longitudinal structural and functional imaging studies seem currently most robust to evaluate progressive impairment in MCI and AD. However, from the perspective of developing countries of the many technologies available, CT head scan and structural MRI imaging are the most useful, widely available and affordable imaging modalities.
